

1 Design inequalities

We can efficiently construct a list of candidate graphs using the base graph method. However, not every generated graph is necessarily solvable. One can check whether a graph is solvable from the set of linear inequalities underlying the graph, which we refer to as the design inequalities.

We recall that a hysteron i is stable under an external field U if:

$$\begin{cases} U > U_i^+(S), s_i = 0 \\ U < U_i^-(S), s_i = 1 \end{cases} \quad (1)$$

To help our notation, we here define that

$$U_i(S) = \begin{cases} U_i^+(S), s_i = 0 \\ U_i^-(S), s_i = 1 \end{cases} \quad (2)$$

We also define the direction r_i as:

$$r_i = 1 - 2s_i \quad (3)$$

so that $r_i = 1$ if $s_i = 0$ and $r_i = -1$ if $s_i = 1$.

We can then rewrite the conditional statement from Equation 1 into a single statement:

$$r_i U_i(S) > r_i U \quad (4)$$

We now consider in detail what the design inequalities of a graph look like, using an example $N = 2$ graph (Fig. 1).

We first consider the inequalities required for the transition $00 \uparrow 01$, which consists out of a single flip of hysteron 2. In order for hysteron 2 to flip before hysteron 1 when the driving U is increased, one must have that $U_2^+(00) < U_1^+(01)$. Next, we must have that the state 01 is stable under the current driving, which is the switching field $U_2^+(00)$. The requirement for state 01 to be stable leads to two more inequalities, namely $U_1^+(01) > U_2^+(00)$ and $U_2^-(01) < U_2^+(00)$.

As a second example, we consider the avalanche $11 \downarrow 10 \downarrow 00$. Analogously to the previous example, we first require for hysteron 2 to be the first to flip down when decreasing the driving U , so that we obtain the inequality $U_2^-(11) > U_1^-(10)$. Next, a set of inequalities is required which describes the stability of the state 10 under the field $U_2^-(11)$. Unlike in the previous example, however, hysteron 1 must now be unstable. Thus, we obtain the set of inequalities $U_1^-(10) \geq U_2^-(11)$ and $U_2^+(10) > U_2^-(11)$.

We can generalize the method for finding the design inequalities to any transition path $S^{(0)} \rightarrow S^{(1)} \rightarrow \dots \rightarrow S^{(1)}$. On one hand, for each transition there is a set of inequalities required to initiate the transition, which is of the form

$$\begin{cases} U_i^+(S) = \min_{s_j=0} U_j^+(S), s_i = 0 \\ U_i^-(S) = \max_{s_j=1} U_j^-(S), s_i = 1 \end{cases} \quad (5)$$

Figure 1: Design inequalities for an example $N = 2$ graph (a). Design inequalities are shown for (b) the $l = 1$ transition $00 \uparrow 01$ and (c) the $l = 2$ avalanche $11 \downarrow 10 \downarrow 00$.

which we can shorten as:

$$r_i U_i(S) = \min_{s_j=s_i} r_j U_j(S) \quad (6)$$

where i is the hysteron that flips. We refer to the set of inequalities that is required to initiate the transition as the base inequalities.

Let us now define the field $U_i(S^{(0)})$ which initiates the transition as U^* . On top of the base inequalities, an additional set of linear inequalities is needed to describe the stability of each of the states $S^{(1)}, \dots, S^{(l)}$ under U^* . For the final state $S^{(l)}$, all hysterons must be stable, so that:

$$r_j U_j(S^{(l)}) > r_j U^* \forall j \quad (7)$$

For the intermediate states $S^{(1)}, \dots, S^{(l-1)}$, all hysterons are stable except for a single hysteron k , for which the inequality flips:

$$\begin{aligned} r_j U_j(S^{(1)}) &> r_j U^* \forall j, j \neq k \\ r_k U_k(S^{(1)}) &\leq r_k U^* \end{aligned} \quad (8)$$

For the general model where the switching fields $U_i^{+,-}(S)$ are independent, we note that the base inequalities are always solvable. This is because there is no

overlap between the sets of inequalities for the individual transitions, since they describe relations between switching fields at the same state $S^{(0)}$. In contrast, the relaxation inequalities describe relations between switching fields at different states, so that it is possible for a combination of transitions to be incompatible even in the general model.
